Modeling sequential data

- Speech recognition
- Machine translation
- Handwriting recognition
- Biological sequences
- Processes originating from the area of business and finance
- Robotics (location of the robot)
- Health monitoring

Sequential processes

- Consider a system with N discrete states. (Some times referred as the system which may occupy one of N states at each time instance t).
- The processes, in which the state evolution is random over time, are called stochastic processes.
- Any joint distribution over sequences of states can be factored according to the chain rule into a product of conditional distributions:

$$p(x_0, x_1, \dots, x_T) = p(x_0) \prod_{t=1}^T p(x_t \mid x_0, \dots, x_{t-1})$$

Example: language modeling

- What is the probability of a sentence: The cat sat on the mat ?
- According to the chain rule:

$$\begin{split} p(\mathsf{The \ cat \ sat \ on \ the \ mat}) &= \\ p(\mathsf{The}) \times \\ p(\mathsf{cat} \mid \mathsf{The}) \times \\ p(\mathsf{sat} \mid \mathsf{The \ cat}) \times \\ p(\mathsf{on} \mid \mathsf{The \ cat \ sat}) \times \\ p(\mathsf{the} \mid \mathsf{The \ cat \ sat \ on}) \times \\ p(\mathsf{mat} \mid \mathsf{The \ cat \ sat \ on \ the}) \times \end{split}$$

 Problem: infeasible amount of data necessary to learn all the statistics reliably.

Markov process

• Let us suppose that the future is independent of the past given the present.

$$p(x_{t-1}, x_{t+1} \mid x_t) = p(x_{t-1} \mid x_t) \cdot p(x_{t+1} \mid x_t)$$

referred as Markov Assumption

• The processes where the next step depends only on the current state:

$$p(x_{t+1} \mid x_0, \dots, x_t) = p(x_{t+1} \mid x_t)$$

are called Markov processes

• Combining the Markov assumption with the chain rule one gets the probability of the whole sequence as:

$$p(x_0, x_1, \dots, x_T) = p(x_0) \prod_{t=1}^T p(x_t \mid x_{t-1})$$

Language modeling with Markov process

- What is the probability of the sentence The cat sat on the mat?
- according to the Markov assumption and the chain rule:

```
\begin{split} p(\mathsf{The \ cat \ sat \ on \ the \ mat}) &= \\ p(\mathsf{The}) \times \\ p(\mathsf{cat} \mid \mathsf{The}) \times \\ p(\mathsf{sat} \mid \mathsf{cat}) \times \\ p(\mathsf{on} \mid \mathsf{sat}) \times \\ p(\mathsf{the} \mid \mathsf{on}) \times \\ p(\mathsf{mat} \mid \mathsf{the}) \times \end{split}
```

• Obviously one has to estimate much smaller number of the parameters.

Markov Chain

- The sequence generated by a Markov process is called the Markov chain
- Usually it is assumed that the Markov chain is time-invariant or stationary this means that the probabilities $p(x_t \mid x_{t-1})$ do not depend on time.
- For example in language modeling the probability $p(\text{the} \mid \text{on})$ does not depend on the positions of these words in the sentence.
- This is an example of parameter tying since the parameter is shared by multiple variables

Markov model specification

• A stationary Markov model with N states can be described by an $N\times N$ transition matrix:

$$Q = \begin{bmatrix} q_{11} & \dots & q_{1N} \\ \dots & \dots & \dots \\ q_{N1} & \dots & q_{NN} \end{bmatrix}$$

where $q_{ij} = p(x_t = i \mid x_{t-1} = j)$

• Constraints on valid transition matrices:

$$q_{ij} \ge 0, \qquad \sum_{i=1}^{N} q_{i,j} = 1, \text{ for all } j$$

State transition diagram

- State transition matrices can be visualized with a state transition diagram
- State transition diagram is a directed graph where arrows represent legal transitions.
- Drawing state transition diagrams is most useful when N is small and Q is sparse.

$$Q = \begin{bmatrix} 0.4 & 0.6\\ 0.7 & 0.3 \end{bmatrix}$$

S. Nõmm (CS TalTech)

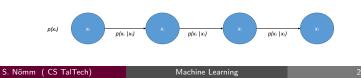

Graphical models

- A way of specifying conditional independencies
- Directed graphical model: DAG
- Nodes are random variables
- A node's distribution depends on its parents
- Joint distribution: $p(X) = \prod_{i=1}^{n} p(x_i \mid \mathsf{Parents}_i)$
- A node's value conditional on its parents is independent of other ancestors

Markov chain as a graphical model

$$p(x_0, x_1, \dots, x_T) = p(x_0) \prod_{t=1}^T p(x_t \mid x_{t-1})$$

- Graph interpretation differs from state transition diagrams:
- Nodes represent state values at particular times
- Edges represent Markov properties

Markov chain training

- Let us assume that training data is given in the form of sequences
- One can count the number of occurrence of any two consecutive values
- For example, we can count how many times occurs the word pair "of the" in the training text.
- For obtaining the quantity p(the | of) we have to divide with the number of times the word "of" occurs in the training data:

$$p(\mathsf{the} \mid \mathsf{of}) = \frac{p(\mathsf{of the})}{p(\mathsf{of})} = \frac{Count(\mathsf{ot the})}{Count(\mathsf{of})}$$

• In general, if $N_{i,j}$ is the number of times the value i is followed by the value j:

$$p(x_t = j \mid x_{t-1} = i) = \frac{p(x_{t-1} = i, x_t = j)}{p(x_{t-1} = i)} = \frac{N_{i,j}}{\sum_j N_{ij}}$$

Markov chain order

- The Markov chain presented in previous slides is called *first-order* Markov model.
- It is also called *bigram* model (especially in language modelling)
- The marginal probabilities $p(x_t)$ are called *unigram* probabilities
- In the unigram model all the variables are independent $p(x_0, x_1, \dots, x_T) = \prod_t p(x_t)$
- One can also construct higher order Markov chains: a second order model operates with trigrams:

$$p(x_t \mid x_0, \dots, x_{t-1}) = p(x_t \mid x_{t-2}, x_{t-1})$$

Hidden Markov models

- Few realistic sequential processes directly satisfy the Markov assumption.
- Markov chains cannot capture long-range correlations between observations.
- Increasing the order leads the number of parameters to blow up
- This motivates the hidden Markov models (HMM)
- In HMM there is an underlying hidden process that can be modelled with a first-order Markov chain
- The data is the noisy observation of this process.

HMM: handwriting recognition

- We can only observe the handwritten character images
- The hidden process models the characters written

HMM specification

There are three distributions:

$$p(x_0)$$

 $p(x_t \mid x_{t-1}), \quad t = 1, ..., T$
 $p(y_t \mid x_t), \quad t = 1, ..., T$

Joint distribution

The joint distribution of the hidden sequence is:

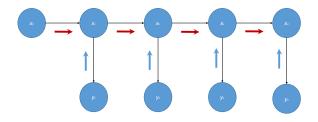

$$p(x_0, \dots, x_T) \mid y_0, \dots, y_T) \propto p(x_0)p(y_0 \mid x_0) \prod_{t=1}^T p(x_t \mid x_{t-1})p(y_t \mid x_t)$$

- Compute marginal probabilities of hidden variables
- Filtering compute the belief states $p(x_t \mid y_0, \dots, y_t)$ online
- Smoothing compute the probabilities $(x_t \mid y_0, \dots, y_T)$ offline using all the evidence
- Find the most likely sequence of hidden variables Viterbi decoding

Filtering

- Computing $p(x_t \mid y_0, \dots, y_t)$ is called filtering, because it reduces noise in comparison to computing just $p(x_t \mid y_t)$.
- Filtering is done using forward algorithm
- Forward algorithm uses dynamic programming this means the algorithm is recursive but we reuse the already done computations.

Forward algorithm

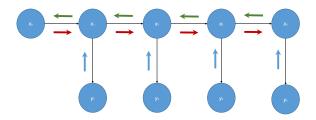

Input:

- Transition matrix
- Initial state distribution
- Observation matrix containing probabilities $p(y_t \mid x_t)$
- Compute the forward probabilities:

$$\alpha_t(x_t) = p(x_t \mid y_{1:t}) = \frac{1}{Z_t} p(y_t \mid x_t) \sum_{x_{t-1}} p(x_t \mid x_{t-1} \alpha_{t-1}(x_{t-1}))$$

Smoothing

- Smoothing computes the marginal probabilities $p(x_t \mid y_{1:T})$ off line, using all the evidence
- It is called smoothing, because conditioning on the past and future data the uncertainty will be significantly reduced.
- Smoothing is performed using forward-backward algorithm.

Forward-backward algorithm

• Break the chain into past and future:

$$p(x_t = j \mid y_{1:T}) \propto p(x_t = j, y_{t+1:T} \mid y_{1:t})$$

$$\propto p(x_t = j \mid y_{1:t})p(y_{t+1:T} \mid x_t = j)$$

• Compute the forward probabilities as before:

$$\alpha_t(x_t) = p(x_t = j \mid y_{1:t})$$

• Compute the backward probabilities:

$$\beta_t(x_t) = \frac{1}{Z_t} \sum_{x_t} p(x_{t+1} \mid x_t) p(y_{t+1} \mid x_{t+1}) \beta_{t+1}(x_{t+1})$$

• Compute the smoothed posterior marginal probabilities

 $p(x_t \mid y_{1:T}) \propto \alpha_t(x_t)\beta_t(x_t)$

- Probabilities measure the posterior confidence in the true hidden states
- Takes into account both the past and the future

Optimal sequence estimation

• Viterbi algorithm computes

$$\hat{x} = \arg\max p(x_0, \dots, x_t \mid y_1, \dots, y_T)$$

• Using dynamic programming it finds recursively the probability of the most likely state sequence ending with each x_t :

$$\gamma_t(x_t) = \max_{x_1, \dots, x_{t-1}} p(x_1, \dots, x_t \mid y_{1:t})$$
$$\propto p(y_t \mid x_t) \Big[\max_{x_{t-1}} \quad p(x_t \mid x_{t-1}) \gamma_{t-1} x_{t-1} \Big]$$

• A backtracking procedure picks then the most likely sequence.

Learning HMM

- Let us suppose the latent state sequence is available during training
- Then the transition matrix, observation matrix and initial state distribution can be estimated by normalized counts

$$\hat{q}_{i,j} = \frac{n(i,j)}{\sum_k n(k,j)}$$
$$\tau_i = \{t \mid x_t = i\}$$
$$\hat{\theta}_i = \frac{1}{\mid \tau_i \mid} \sum_{t \in \tau_i} y_t$$

Learning HMM

- Typically one don't know the hidden state sequences
- EM algorithm is used, it iteratively maximizes the lower bound on the true data likelihood
- E-step: Use current parameters to estimate the state using forward-backward
- M-step: Update the parameters using weighted averages
